
Coding Agents for Coding Theory

Abraham Yeung

ayeung16@stanford.edu

Abstract

We spent five weeks using an LLM coding agent on open problems in coding theory: finding large sets of four-letter words, such as DNA barcodes, that stay far apart in edit distance. The agent wrote the verifiers and search code; a human chose the problem and set the verification protocol. Restricting the search to codes with a prescribed symmetry, a classical technique, shrank the problem about fourfold and raised the best known code of length 6 and minimum edit distance 3 from 114 to 120 words ($E_4(6, 3) \geq 120$). The same pipeline improved twelve further lower bounds at lengths 6 to 9 and distances 3 to 6 (Table 2).

We give the failures equal space. Our own search stopped at 116 and recorded the last symmetry class as topping out at 112; a second agent session, running the same search with a better operator, found the 120. A later verdict that the method did not carry over to length 7 was wrong for the same reason, and an earlier instance (Section 5) cost three weeks. Each time, an intermediate result was written down, never rechecked, and treated as a fact that ruled out further search. Checking final outputs, as our protocol required, does not catch such errors.

1 Introduction

LLM coding agents can search large combinatorial spaces. The harder question is whether their output can be trusted. Final constructions can be verified. The intermediate conclusions an agent accumulates along the way, such as which symmetry classes have been searched and which cells are exhausted, usually are not, and those conclusions shape a project’s trajectory. This paper describes one five-week project in which agent sessions found genuine improvements to published bounds in coding theory, and also recorded wrong intermediate conclusions that hid one of those improvements for three weeks. We give the failures as much space as the results because, for anyone deciding how to supervise such an agent, the failures are more useful.

The results. The largest known quaternary code of length 6 with minimum edit distance 3, equivalently a single-edit-correcting DNA barcode set, has 120 codewords. The maintained table of bounds gives 114–176 [3], the lower value from a 2011–2012 evolutionary search [1; 2]. A recent LLM-guided search reports 113 for the same problem [7]. The 120 comes from formulating the problem as maximum independent set on a 4096-vertex confusability graph and searching over codes invariant under the Klein four-group acting on the alphabet.

Verification ran in fresh processes: reimplementations sharing no source with the search find a minimum pairwise distance of exactly 3 and zero colliding edit-balls. The confusability graph was differentially tested against the definition on all 8,386,560 vertex pairs, and reproduces the table’s exact published entries ($E_4(3, 3) = 4$, $E_4(4, 3) = 16$, $n = 5$ sweep at the published 44). Twelve further lower bounds improved (Section 4, Table 2), at $n = 6$ to 9 and d up to 6, those at $n \geq 8$ once a C orbit-graph builder made the sizes tractable. Figure 1 (Appendix B) dates each record.

2 Setup

A code $C \subseteq \Sigma^n$ over $|\Sigma| = q$ has minimum edit distance d if every pair of distinct codewords requires at least d insertions, deletions or substitutions to interconvert; $E_q(n, d)$ is the maximum size of such a code. Maximising $E_q(n, d)$ is a maximum independent set (MIS) problem on the *confusability graph*: the vertex set is Σ^n ($4^6 = 4096$ vertices at $n = 6$), with two words adjacent when their edit distance is less than d . At $n = 6$, $d = 3$ the graph has 392,358 edges, and the strong MIS solver ReduMIS [6] plateaus at 113.

What the agent did and did not do. The agent was Claude Opus 5 via Claude Code, an LLM with shell access rather than a bespoke mathematical system. It wrote the verifiers and search code and drove off-the-shelf solvers (HiGHS, CaDiCaL, SciPy/CVXPY, ReduMIS [6]). A human chose the problem, set the protocol and redirected between sessions. The agent did the implementation and interpretation, and chose methods from the protocol’s escalation order (Appendix A lists who proposed what). That protocol, which we call verifier-first, was a project instructions file loaded into every session. It required two independent verifiers with different representations and no shared code, the first written and tested on corrupted objects before any search began. It also required reproducing known published values before searching new cells, and re-verifying every saved bound in a fresh process. In the shipped version, its escalation order puts prescribed-symmetry search right after brute force and moves up a rung when the current one plateaus. The file was rewritten during the project, so we cannot tell whether that advice came before the agent first used the method. The decisive run came from a second agent session with no shared context that audited our repository (Section 3). It used its own implementation of the local search of Andrade, Resende and Werneck (ARW) [5]. Our Python operator already had the same (1,2)-swaps and plateau moves, so the difference lay in implementation details we did not isolate. Sessions did not re-read all earlier sessions. This matters for Section 5, because conclusions written in one session became invisible constraints on later ones. The verifiers are independent in representation (edit balls, two Levenshtein tables, Myers bit-vectors) but not in authorship, and the differential test against the definition on all word pairs guards their shared assumptions.

Related work. The $d = 3$ cells were recently attacked by LLM-guided search [7]. The checks we use are standard testing ideas (known-answer instances, metamorphic and differential testing), normally applied to a system’s outputs. What cost this project three weeks was an error in intermediate state and its summaries, which output checks never see.

3 What worked

Prescribed symmetry. The mathematical core is prescribed-automorphism search in the Kramer–Mesner line [4]: choose a group, require the code to be invariant under it, and search orbit representatives instead of individual words. At $n = 6$ the natural symmetry group is $S_4 \times C_2$ (the 24 permutations of the four-letter alphabet, times word reversal, giving order 48). We do not claim this is the full automorphism group of the confusability graph, which we did not compute. The group has 33 conjugacy classes of subgroups. Twenty-two are product-form (a permutation subgroup H , optionally paired with reversal). The other eleven are *diagonal*: they contain elements that pair a permutation with reversal, and cannot be written as H or $H \times C_2$. Three of the order-4 classes act freely on Σ^6 . In each, the search collapses from 4096 words to 1021 usable orbits (those whose elements are pairwise at edit distance ≥ 3), and every orbit has exactly 4 elements, so invariant code sizes are multiples of 4 and nothing lies between 116 and 120.

What our search missed. Our first sweep covered 30 of the 33 classes and gave each four seeds; the other three, missed by our enumeration, were searched later and reach 104. Two of the three free-acting classes returned 116; the third returned 112 on all four seeds. We recorded 112 as its maximum. Both parts of that recording were wrong. Re-running the same class with our operator at ten ten-minute seeds returns 116 on five of them. Then the second agent session ran its ARW implementation on the same orbit graph. It reached 116 on every seed within a minute, and 120 on two of six seeds. We then reimplemented that operator in C (`search/mis_ils.c`, about 10^3 times more iterations per second than our Python). It reproduces the 120 and finds 120s in both C_4 classes, so all three free classes contain one. Whether a seed reaches 120 is decided early: fifteen ten-minute

seeds on the free classes all returned 116, while thirty one-minute seeds on the V_4 class returned 120 four times, so more seeds beat longer ones. Those rates belong to the stronger operator. The original four-seed sweep used our own operator at 128 seconds per seed, and that operator never reaches 120 at any budget we tried. The sweep was underpowered even for 116, and its “tops out at 112” was a small sample recorded as settled fact. Nothing reached 124. A numerical, uncertified Lovász theta value on the orbit graph, about 45 orbits (180 words), is too loose to say whether a 124 exists.

The instance reduction is real. Our operator gets 111 on the raw graph at 180 core-minutes and 116 on the orbit graph at 8.5, and the stronger operator gets 120 on the orbit graph but only 114 on the raw one. ReduMIS on the same orbit graph returns 116 on each of three single-threaded ten-minute seeds, against 112–113 on the raw graph, where its seeds stopped on their own after 4.6–6.1 minutes; at the same 30 core-minutes, the C operator returns 120 on four of thirty one-minute seeds. So the reduction lifts all three operators to 116, and the step to 120 needs a stronger operator on the reduced instance, since neither alone reaches it at $n = 6$. The ranking is not stable in n . At $n = 8$ ReduMIS reaches 1124–1132 on the V_4 orbit graph against the C operator’s 1148, and at $n = 9$ it reaches 3760 against 3724 (Table 2).

Calibration cells. Verification shows that an artifact is valid. It says nothing about whether a search was strong enough for a negative result to mean anything, and most of a project’s output is negative results. We propose including in every batch one cell with an independent reference; ours is the unrestricted problem, whose exact value is open, with ReduMIS’s 113 as reference. Table 1 shows why: a sweep over 15 previously unexamined cells returned a plausible spread of values up to 100, while the same solver scored 99 on the unrestricted problem, where 113 is attainable. The batch was measuring the solver rather than the cells, so we discarded it. The check is not sufficient, since the sweep that under-searched the winning class passed its calibration cell. It detects a broken solver but not an under-budgeted one.

Table 1: Calibration across three runs, and (right) the compute-response of the repaired operator, nearly flat over 6–60 core-min; the 150 row is our earlier raw-graph local search, for reference only.

		the three runs			operator vs. budget	
	run	core-min	best	calib.	budget	calib.
1	original operator	6	100	99	6 (broken op.)	99
2	repaired operator	60	112	110	6	109
3	later sweep, same op.	20	116	109	15	109
					20	109
					60	110
					150 (<i>raw-graph ILS</i>) 111	

The check needs a decision rule, and an absolute threshold is the wrong one. Run 3, which produced the 116, scored 109, *below* the 110 that licensed trusting the operator in run 2, so a fixed cutoff would have discarded the run that found the 116. Normalising by compute avoids this. The right-hand columns plot the repaired operator against budget: 109 at six core-minutes and 110 at sixty, a $10\times$ increase buying one codeword. The curve has four points; two share their configuration with runs 2 and 3, so they are not independent of what is being judged. The curve is close to flat, and against it run 1’s 99 at six core-minutes is ten low. So we judge a run by its distance from the compute-response curve instead of from a fixed number. The curve costs four short runs on a known cell.

A cheaper variant needs no known answer. Conjugate subgroups give isomorphic problems, so cells within one conjugacy class must report equal optima, and any spread flags the solver. Run 1 returned 88, 87, 86, 84, 88, 83 on six isomorphic problems inside a single class.

4 Where it did not work

$n = 7$: **first a negative result, then not.** Applied unchanged to $E_4(7, 3)$, whose record is 356, the best over 30 of the 33 invariance classes was 355. (Three classes our first enumeration missed, which need three generators, were searched afterwards and reach 340.) Our notes recorded this as “the method did not transfer,” then qualified it as a statement about our search rather than about the cell, since the same operator had already under-searched the $n = 6$ winning class.

The qualification was correct. The C operator, on the same orbit graphs, returned 358 on both of its ten-minute seeds in the order-6 class that had given 355, and 359 in the reversal-only class (6844 orbits). That code consists of 164 reversal pairs and 31 palindromes. Each passed all four verifiers and a from-scratch distance check. Three further fifteen-minute seeds of the same operator on the order-6 class all gave 355, the stalling of long seeds seen at $n = 6$. Twenty-six further two-minute seeds spread 355–364, and the 364 is the value in Table 2.

Other distances. Nothing in the method is specific to $d = 3$: symbol permutations and reversal preserve edit distance, so the same 33 classes act on every conflict graph “ $\text{lev} \leq d - 1$.” We built a general- d version (a C graph builder and two independent verifiers with a 3463-check accept/reject suite) and first checked it on the table’s exact cells, which it must reproduce and must not exceed: $E_4(5, 3) = 44$, $E_4(5, 4) = 11$, $E_4(6, 5) = 8$ and $E_4(6, 6) = 4$ all came back exactly. $E_4(6, 4)$, tabled 28–32, then gave 30 in three classes, and a MaxSAT solve of one of those orbit graphs reports 30 as the optimum within that class; $E_4(7, 4)$, tabled 65–128, gave 72 in two order-8 classes. Each took under an hour including graph construction. The same pipeline then ran at $n = 7$ to 9 and at d up to 6. The winning class differs by cell (Table 2), and there was no shortcut to trying them all. A third operator, NuMVC, trailed both others everywhere.

Table 2: Every lower bound this project improved, with a symmetry class containing the record (Appendix C gives each code’s full stabiliser), the usable-orbit count of that class, and how many seeds at the stated budget reached the value (C operator unless marked ReduMIS). The four bounds above the rule were improved first; the rest came from the same pipeline extended further, with $n \geq 8$ built by a C orbit-graph builder validated edge-for-edge against the Python one. Four values are class optima as reported by exact solvers ((6, 4) by MaxSAT, the others by maximum clique of the compatibility graph); none has a checked certificate.

cell	published	new lower bound	class	orbits	seeds
$E_4(6, 3)$	114–176	120	V_4 (free)	1021	8/96 at 1 min
$E_4(7, 3)$	356–614	364	$C_3 \times C_2$	2218	2/26 at 2 min
$E_4(6, 4)$	28–32	30	diagonal, order 4, optimum	518	3/3 at 26 s
$E_4(7, 4)$	65–128	72	diagonal, order 8	1277	11/11 at 1–2 min
$E_4(8, 3)$	1132–2340	1148	V_4 (free)	16381	1/20 at 10 min
$E_4(9, 3)$	3451–9360	3760	diagonal C_4 (free)	65531	ReduMIS, 2/7 at 15–30 min
$E_4(8, 4)$	176–512	200	diagonal, order 8	6500	2/24 at 10 min
$E_4(9, 4)$	495–2048	520	diagonal, order 8	28627	4/10 at 15 min
$E_4(7, 5)$	18–24	20	V_4 (free), optimum	3568	13/13 at 0.5–1 min
$E_4(8, 5)$	38–96	44	V_4 (free)	15649	2/10 at 10 min
$E_4(9, 5)$	97–384	100	diagonal, order 8	13143	4/4 at 15 min
$E_4(8, 6)$	14–32	16	V_4 (free), optimum	12055	8/8 at 5–10 min
$E_4(9, 6)$	27–128	32	diagonal, order 8, optimum	5813	2/2 at 10 min

SAT and ILP. These end the protocol’s escalation order. For constructions they returned nothing usable. SAT reported UNKNOWN after 462 s and 389 s on instances known to be feasible (binary deletion codes at $n = 11$, from the same project), and the ILP returned unconverged incumbents on the cells here. For certificates the same tools were indispensable: drat-trim-verified UNSAT proofs, including a proof that the A_4 -invariant optimum is exactly 112, and LP duality reproducing 24 of 24 published LP relaxation values as exact rational certificates. The ranking of tools depends on direction. Heuristic local search built every construction, and formal methods produced every checked certificate. The four class optima of Table 2 have none.

5 The most expensive error

Three weeks before our first record, the 116, a sweep reported “best invariant code 112, proven optimal in the A_4 class” over what it described as all subgroups. Four defects were behind that sentence. The parameterisation expressed invariance as “ $H \leq S_4$, optionally with reversal,” reaching only the 22 product-form classes. One of the 116-word codes found later lives in a diagonal class it could not express. And a size cap skipped 15 of the 60 (subgroup, reversal) cells of that parameterisation, precisely the weakest-symmetry ones.

Inside the cap, the MILP returned unproven incumbents on cells it could not finish, and the summary dropped their status. Those last two defects are the instructive ones. Three conjugate cells, isomorphic problems that must share an optimum, were reported as 100, 92 and 8 for a quantity now known to be ≥ 120 . The results file *did* record `proven_optimal_invariant: false` for all three, and the conjugacy check of Section 3 would have flagged the spread. (The A_4 optimum really is 112; the error was “all subgroups.”) The flag was present in the data and absent from the summary, and the summary is what a human collaborator reads. None of the four raised an error. All produced plausible numbers, so a protocol that checks outputs never questioned them. The protocol had the same gap, since the ground-truth verifier did not cover this problem family until ten days after our first record, the 116. We keep the description “verifier-first” because that is what the protocol specified, not what the 116 received at the time.

Here the agent wrote conclusions faster than its supervisor re-read them, and those conclusions narrowed the search without anyone noticing. No search that trusted the recorded summary would have revisited the class that held the bound. The fix is cheap. Recheck settled conclusions on a schedule, and record unproven solver output as `unknown` rather than as a value. The protocol had no such rule until 7 September. Our own first correction, which added the diagonal classes, was itself incomplete (it enumerated 30 of the 33) and was caught only by separate review sessions.

6 Limitations

This is a single case study: one project, one problem family, one human supervisor, and no comparison across projects. The 120 came from a second agent session rather than our main search, and most later bounds from our C reimplementation of that operator ($E_4(9, 3)$ from ReduMIS). The operator comparison of Section 3, which includes ReduMIS on the orbit graphs, and the NuMVC run are the only controls we have. They show that the bounds need both the reduced instance and a strong operator, and that which operator is strongest depends on the cell. We cannot cleanly isolate how much of the result is attributable to the agent versus a conventional search pipeline using the same mathematical machinery. The key algorithmic components (prescribed symmetry, the ARW operator) predate LLMs, and the agent’s contribution was the engineering around a classical method, not a new method.

The run records sum to about 130 core-hours on one laptop. Session counts, API cost and human redirects were not logged, and intermediate conclusions were not counted as they were written, so “three times” has no denominator. What we can say is that the three negatives that pruned the search all turned out wrong when re-run at a larger budget, while others, such as the absence of a 124 at $n = 6$, held. The calibration rule has no fixed tolerance and has only been tried on the runs in Table 1, and the remedies themselves are untested. The failure modes are not specific to language models. Dropped provenance and underpowered sampling happen in any computational project, and our claim is only that here the agent wrote summaries faster than its supervisor re-read the logs. Every result is an improved lower bound, no upper bound changed, and the incumbents are unverified heuristic claims whose codeword lists were never published, so their long standing may partly reflect how few have attacked them. The logs are self-reported by the system under study, so we release them: the supplement (<https://github.com/Abraham-y/coding-agents-coding-theory>) ships the codes, all four verifiers, the defective sweep, the protocol document and every run record, and one script re-verifies every claimed bound in minutes.

7 Conclusion

The mathematics that produced the bounds is classical prescribed-automorphism search. Which operator and symmetry class worked best changed from one (n, d) to the next, and the free action fixed sizes at multiples of four without causing the escape from the incumbent. The contribution to AI methodology is the failure analysis. Three times in this project a conclusion was recorded, never rechecked, and turned out to be hiding the answer: a sweep whose summary dropped the solver’s “unproven” status, a four-seed result read as a property of a class, and a “does not transfer” verdict that was a property of the operator. A verifier-first protocol catches errors in final outputs but not in the intermediate state that decides which outputs to pursue, and we expect that gap to matter more as agents run for longer.

A Who proposed what

Compiled from Sections 2–5 and the project notes. “Agent” means the main agent sessions; “second session” means the independent session that audited our repository and found the 120; “review sessions” are other independent adversarial-review sessions.

Decision or component	Source
Problem: open cells of the quaternary edit-metric table	Human
Protocol: verifier-first rules and escalation order	Human
Redirects between sessions	Human
Prescribed-symmetry search, a classical method [4]	Agent, within the protocol’s escalation order, which as shipped lists it second; we cannot date that entry against the agent’s first use
Verifiers, search code, orbit-graph builders, and C implementations of the ARW operator and NuMVC	Agent
Recorded conclusions, including the 112 ceiling and “did not transfer”	Agent
Its own ARW implementation [5] on the $n = 6$ orbit graph, which found the 120	Second session
Catching that our first correction enumerated only 30 of the 33 classes	Review sessions
DRAT proof that the A_4 -invariant optimum is 112	Review session
Solvers: HiGHS, CaDiCaL, drat-trim, RC2 (python-sat), SciPy/CVXPY with SCS, networkx, ReduMIS [6]	Existing tools

B Timeline

Figure 1: When each record was set, by calendar day, from the dated entries in the project notes (notes/sota.md, in the supplement). This is calendar time, not machine time: run records lack consistent timestamps and compute fields, so they cannot be placed on a machine-time axis. (a) Our $E_4(6, 3)$ records against the published 114; the vertical line marks the sweep of Section 5. (b) Cells where we held a bound above the published one, at the end of each day. Twelve of the thirteen records date from the last two days, once the ARW operator and the C orbit-graph builder were in place.

C The thirteen codes

Each list is the complete code; sha256 is over the sorted words, one per line, each line newline-terminated. Each was re-verified from the definition in a fresh process (pairwise Levenshtein distance $\geq d$). The same lists ship as plain-text files in the supplement, with the verifiers.

$E_4(6, 3) \geq 120$, **120 words**. Stabiliser in $S_4 \times C_2$: Klein four-group V_4 on symbols, no reversal. sha256 adeaa3604074f5f2b42ece623e45df96f9521650b98fb11a7182321fbc5c3576.
